1 Introduction

In this report we describe a *reverse communication interface* for the software implementing the iterative methods described in the *Templates book* [2]. Reverse communication is a technique by which we can hide the implementation details of various operations from the implementation of the iterative method. This allows us to (a) remove references to the user-prepared array or data structure containing the matrix within the iterative solver, and (b) uniformly take care of the various components that can be changed by a user. These include implementation details of matrix-vector operations, vector operations, stopping tests, and norm computations.

Section 2 discusses the concept of reverse communication with the help of an example from the Templates code. Section 3 explains the use of iterative methods under this scheme. Section 4 discusses refinements and enhancements that we have planned. Finally, Section 5 provides information on how to obtain the software and the Appendix presents an example code.

2 Reverse Communication

In this section, we present the motivation behind reverse communication. We then describe how to use the interface and discuss its advantages and limitations.

2.1 The Interface

All iterative methods have one or more of the following operations:

- matrix-vector multiply (transpose and/or nontranspose), and
- preconditioner solve (transpose and/or nontranspose).

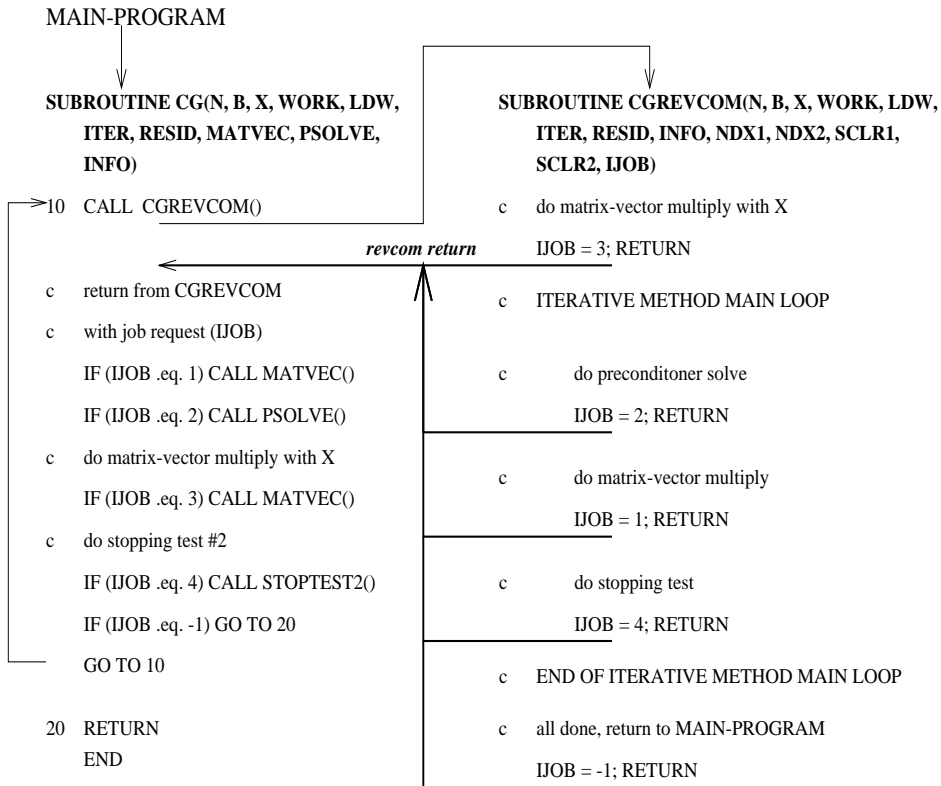

These operations account for a large portion of the computation and thus are the focus of most optimization efforts. Optimization can involve significant changes in algorithm and data structures. Further, different problems may require different storage formats for their associated matrices and vectors.

The primary aim of reverse communication (REVCOM) is to isolate the matrix-vector operation. Such operations are performed by routines that the user supplies on data structures that are most natural to the problem at hand [3]. The idea of reverse communication is not new. In this approach, the iterative method subroutine does not need to know anything about the data structure or other requirements of the matrix-vector or preconditioner operations. Whenever the iterative method subroutine needs the results of one of the operations, it returns control to the user's subroutine that called it. The user's subroutine then invokes the module that performs the operation. The iterative method subroutine is invoked again by the user with the results of the operation. This interaction is explained in Figure 1 with the help of the conjugate gradient (CG) iterative method.

Here, CGREVCOM implements the iterative method, and CG implements the user subroutine that manages the requests from CGREVCOM. The user's main program invokes CG as before. The CG subroutine invokes CGREVCOM; and during this call, the CG method and *resume logic* are initialized. One step of the initialization of CG is a matrix-vector multiply. At this point in the flow of control, the job indicator variable (IJOB) is set to 1, and control is returned to CG. In CG, control resumes at the case statement. When IJOB = 1, the MATVEC subroutine is invoked. On return from MATVEC, control returns to the line with label 10. CGREVCOM is then invoked, this time with the results of the matrix-vector multiply. Inside CGREVCOM, the *resume logic* is used to determine where execution should resume. A similar sequence of actions occurs within the ITERATIVE METHOD MAIN LOOP when results of the preconditioner solve and matrix-vector multiply are required. For the former, CG invokes PSOLVE; for the latter, it invokes MATVEC.

Data is exchanged by using the following parameters of CGREVCOM.

1. *IJOB*: used by CGREVCOM to tell CG of the operation it needs done, and used by CG to tell CGREVCOM whether the current invocation is an initialization call or a resume call.
2. *NDX1*, *NDX2*: used by CGREVCOM to tell CG of the indices of the operand and to identify the destination vectors to be used in the operations. This is for the cases when these vectors are located in the WORK array. If either is a named

Note 1: Diagram only represents reverse communication interactions. STOP END

Note 2: CGREVCOM() logic to resume execution at appropriate place not shown.

Figure 1: Interactions as a result of reverse communication

vector (e.g., X), a different opcode is used to indicate that the operation has to be done by using vector X .

3. *SCLR1*, *SCLR2*: used by CGREVCOM to tell CG what the scalars in the matrix-vector multiplication are. The Templates code currently uses *dgemm* from LAPACK, and that routine requires two scalar arguments—*alpha* and *beta*.

Note that we have implemented reverse communication only for matrix-vector operations. Vector-vector operations (dot product, norm computation) operate on contiguous memory locations, and there is not any variation in the implementation of such operations. However, if required, these vector-vector operations can also be easily provided in the reverse communication interface.

2.2 Another Use of the Interface

REVCOM provides a *client-server* type of interface between the iterative method routine and the interface. That is, the reverse communication asks for services (i.e., is the client), and the interface level provides the requested services (i.e., the server). This model allows us to abstract from the iterative method routine all pieces of code that are liable to change as a result of user requirements. An important example is the above discussion on moving the matrix-vector operations out of the iterative method routine.

In the same vein, we can abstract the stopping test, too. It is generally accepted that there is not one best stopping test for a given combination of user problem and iterative method. Thus, we can use the REVCOM interface to allow the user to change stopping tests quite cleanly. Without such an interface, all changes would have to be made directly in the iterative method routine. Since this routine can be complicated, there is an increased risk of introducing collateral errors.

The stopping test was included in the interface by making the following modifications:

- A job code was created with which the client can request the stopping test to be performed.
- Different stopping tests may operate on different vectors. Further, only the client routine knows the layout of the vectors. Therefore, the server, depending on the stopping test, has to tell the client which vector's indices it needs. This step is taken before the *init* call to the client routine, by setting the NDX1 and NDX2 parameters to appropriate *codes*. These codes (one for each vector) are defined by the client and copied by the server. This mechanism is possible because the workspace, WORK, can also be referenced in the server routine.
The server performs the stopping test and conveys the result to the client via the INFO parameter. A value of 1 indicates a successful test.
- The client, during the *init* call, records the indices needed by the server in local variables NEED1 and NEED2. Subsequently, every time it requests the stopping test to be performed, it sets output parameters NDX1 and NDX2 to NEED1 and

SUBROUTINE CG()	SUBROUTINE CGREVCOM()
c Codes for CGREVCOM's vectors.	c Alias workspace columns.
c 1 == R; 2 == Z; 3 == P; 4 == Q;	R = 1; Z = 2; P = 3; Q = 4
c -1 == ignore; any other == error	IF(NDX1.NE.-1) THEN
NDX1 = 1	IF(NDX1.EQ.1) THEN NEED1 = ((R - 1) * LDW) + 1
NDX2 = -1	ELSEIF(NDX1.EQ.2) THEN NEED1 = ((Z - 1) * LDW) + 1
IJOB = 1	ELSEIF(NDX1.EQ.3) THEN NEED1 = ((P - 1) * LDW) + 1
10 CALL CGREVCOM()	ELSEIF(NDX1.EQ.4) THEN NEED1 = ((Q - 1) * LDW) + 1
⋮	ENDIF
⋮	c Similar code for NDX2/NEED2

	c Request stopping test
	NDX1 = NEED1
	NDX2 = NEED2
	RLBL = 5
	IJOB = 4
	RETURN
	⋮

Figure 2: Actions for REVCOM stopping test

NEED2, respectively. For the CG algorithm, with stopping criterion 2 from the Templates book (i.e., $\|r^{(i)}\| \leq stop_tol \|b\|$), the actions are shown in Figure 2. In the client routine, the code for the stopping test is replaced by code for setting the job code in IJOB, resume label in RLBL, and control returned to the server. When the client is reinvoked after the stopping test, it tests INFO to check whether the stopping test was passed.

2.3 Comments on the Interface

The subroutine (CG in Figure 1) that implements the reverse communication interface must be provided by the user. Apart from any other code, it must contain the GOTO and the IF statements, since these implement the reverse communication feature. Users can use CG and corresponding routines for other iterative methods as templates for their own code.

As mentioned above, the purpose of the REVCOM interface is to isolate the iterative method subroutine from the implementation details of certain operations. A side effect is the slightly unnatural programming style that it imposes. In standard Fortran 77, comparable functionality can be achieved by (a) using COMMON blocks, or (b) passing user subroutines to the iterative method subroutine. COMMON blocks allow for global variables that, for software engineering reasons, are not the preferred means for sharing data. Further, since multiple processes might read/write the same block, memory

consistency requirements discourage the use of COMMON blocks. With option (b) one drawback is that we do not get the same level of isolation as with REVCOM. Another is that the calling sequence has to be frozen¹. In comparison, the REVCOM interface provides us with a rational framework for incorporating different matrix storage formats and different implementations of the operations.

Programs written with the REVCOM framework are as clean, easy to develop, and easy to maintain as those without. There is only a one-time overhead of learning the REVCOM protocol for interactions between the iterative method subroutine and the reverse communication interface subroutine.

The overheads resulting from the REVCOM interface are as follows:

1. SAVE statement in the iterative method subroutine. A cost reduction can be achieved by finding a smaller subset of CGREVCOM variables that need to be SAVE'd. However, to some extent this overhead will persist.
2. Cost of RETURNS from CGREVCOM to CG, and CALL to CGREVCOM from CG. The amount of CALL/RETURN overhead depends on the problem size. If the problem size is small, the number of iterations is small (fewer CALL/RETURNS), and therefore this overhead is small. Larger problems entail more iterations and thus greater overhead. However, the ratio of this overhead to execution time is a constant.

3 Use of Reverse Communication

The top-level calling sequence for the iterative method depends on the user's specification of the matrix-vector multiply, preconditioner solve routine(s), and data structures for the various matrices. As such, the user's subroutine implementing the reverse communication interface must be given all the details it needs to perform the operations requested of it. In our example codes, since we are still using COMMON blocks, the top-level calling sequence remains the same. The call to (for example) the CG routine is as follows:

```

      CALL CG( N, B, X(1,1), WORK, LDW, ITER(1), RESID(1),
$           MATVEC, PSOLVE, INFO(1) )

```

In the reverse communication scheme, the CG subroutine now contains the following call:

```

      CALL CGREVCOM(N, B, X, WORK, LDW, ITER, RESID, INFO,
$                NDX1, NDX2, SCLR1, SCLR2, IJOB)

```

¹In [1] a case is made that a standard calling sequence can be found for the major components of most iterative methods. This would make it possible to write a general iterative package based on user-supplied routines for the matrix operations. However, this is still less general than the REVCOM approach.

The calling sequence to subroutines at this level is fixed and independent of the data structure.

The user must provide implementations of the various matrix-vector operations and stopping tests required by the iterative method. These implementations should adhere to the prescribed calling sequence. If they do not, the reverse communication level (CG in the above example) subroutine will have to be suitably modified. We note that any changes will be restricted to this subroutine.

Note that we have hard-coded the codes for the vectors in supporting stopping tests in the REVCOM interface. The justification is that the iterative method will change very rarely. Further, any changes in its vectors will require commensurate changes in the interface level. The only requirement is that if any changes are made, the encoding *table* in the interface routine must also be updated. This risk can be eliminated by using *include* files (not standard Fortran 77).

The stopping test implementation depends on the user. The only constraint is that after the stopping test has been computed, and before the iterative method is invoked again, the parameter INFO should contain a 1 if the stopping test was successful, and any other integer if the test was not successful. The example code STOPTEST2.f can be used as a template.

In the previous release of the Templates code, the subroutine corresponding to an iterative method (*itmeth*) resided in file *itmeth.f*. For the reverse communication interface, each *itmeth* has two files; *itmeth.f* which implements the reverse communication interface, and *itmethREVCOM.f* which contains the iterative method skeleton. As such, these changes are invisible to the user.

4 Future Work

A number of improvements can be made in the current implementation, in particular:

- more comprehensive error reporting,
- examples with different storage formats,
- more preconditioners,
- a cookbook explaining how to customize templates for a data format and stopping test, and
- parallelization (selecting suitable data formats; parallel implementation of MATVEC, PSOLVE, SAXPY, NORM, etc.).

We plan to investigate these in future releases.

5 Obtaining the Software

The software implementing the Templates algorithms is available (in Fortran in double precision) from netlib, a public domain software repository. To retrieve the software, send e-mail of the form

```
mail netlib@ornl.gov
```

On the subject line or the body, type

```
send (enter shar filename here) from templates
```

shar filename	contents
<u>dftemplates.shar</u>	Double Precision Fortran 77 routines

The shar file will be returned via an automatic e-mail handler. Save it to a file called (shar filename). Type sh (shar filename). The files described above will be unpacked in the current directory.

The files may also be obtained via anonymous ftp as follows:

```
ftp netlib2.cs.utk.edu

ftp> cd templates
ftp> binary
ftp> get dftemplates.shar
```

In addition, the file may be acquired through the Web at the URL <http://www.netlib.org/templates/index.html>.

Appendix: Example Code

This appendix contains the REVCOM code for the CG algorithm. The methods use stopping criterion #2. The structure of the matrices is made available to MATVEC, PSOLVE via a COMMON block in the main program.

5.1 CG.f

```
*
      SUBROUTINE CG( N, B, X, WORK, LDW, ITER, RESID, MATVEC,
$           PSOLVE, INFO )
*
* -- Iterative template routine --
